I. Introduction

In May 2008 the Toronto Stock Exchange composite index (TSX) stood at 14,715. Nine months later it had fallen to 8,123, a decline of 45%. Billions of dollars in household wealth, in the form of stocks, mutual funds, and pension assets, were wiped out. The accompanying slump also reduced the value of business equity, as well as house and other real estate values. Meanwhile workers, many of whom had taken on sizeable debts in the preceding boom, were thrown out of work, often with little in the form of liquid assets to cushion the blow. Thus the worldwide financial and economic crisis of 2008-09 has posed major problems for the economic security of many families and households in Canada.

The purpose of this short paper is to explore some of the impacts on economic security of asset price changes since Statistics Canada's last Survey of Financial Security (SFS) was conducted in May-July 2005. This is a complex topic that could be approached in various ways. Here we will ask what impact observed asset price declines would have had on household wealth and security in the absence of any change in asset quantities. Although an interesting exercise, this is clearly also a partial one. Changes in asset prices induce changes in asset demands, and quantities also change in response to other factors, for example interest rates and employment. A full analysis of the impact of wealth changes on economic security over the last couple of years would have to take quantity as well as price changes into account. But that is beyond the scope of this paper.

The paper is organized as follows. The next section briefly sketches the magnitude of asset price changes since the 2005 SFS and lays out asset and debt holdings according to after-tax income quintiles of Canadian families in 2005. Section III then performs various experiments to see how these assets and debts would have been affected by the rise of prices from 2005 to their peak in the summer of 2008, and by the subsequent price declines. Section IV looks at security impacts from a different perspective, assessing the distribution of asset and wealth impacts across families, in order to examine differences in patterns of vulnerability.

II. Ingredients

Asset Price Changes

Table 1 shows some of the key information on asset price changes in Canada since 2005. It shows values at three points in time: June 2005, the midpoint of the May-July 2005 period when the SFS was in the field; May 2008 when the TSX peaked; and February 2009 when the TSX hit its lowest point, before the recent rally. While house prices peaked a little later than the TSX, in August or September according to the two indexes reported here, in May 2008 house prices were very close to their peak. Also, the amplitude of proportional changes in house prices is much less than that of stocks. Thus it seems sensible to regard May 2008 as the peak for asset prices that are relevant to families in Canada.

While most of the stocks Canadian families hold, directly or indirectly (e.g. through pension plans), are likely listed on the Toronto Stock Exchange, there are other exchanges in Canada, some stocks are unlisted, and Canadians also hold some U.S. and foreign shares.

Unfortunately there do not appear to be any readily available estimates of how Canadians' stock holdings break down across these different categories. Even if such estimates were available, there would be additional difficulties. For example, exchange rate changes may have a substantial effect on the value of foreign stocks, or no impact at all if the investments are hedged.

Taking the non-TSX stock price changes explicitly into account would add some nuances to this exercise, but it is unlikely that it would alter conclusions too greatly. The S&P 500 rose 30% from its June 2005 value of 1,191 to a peak of 1,549 in October 2007 and then fell 53% to 735 in February 2009. Thus U.S. stocks peaked earlier than Canadian, did not rise quite as much, and fell more. Most Canadians who invested in U.S. stocks must have suffered more than those who limited themselves to domestic shares over the period 2007-09. This effect would have been enhanced for those who did not hedge their investment for exchange rate changes, since the Canadian dollar also rose from 80.6 cents U.S. at the end of June 2005 to

almost exact parity in May 2008, and then after rising to \$1.10 in July 2008 had fallen to 80.3 cents in February 2009.

An important item in personal balance sheets, as we shall see, is business equity. There is no price index for the value of private business, of course. It is clear, however, that this value rose during the boom and has fallen in the bust. In the work reported in this paper it is assumed that proportional changes in business equity were the same as those in the TSX. This assumption should appeal to those who believe the stock market does a good job of reflecting the true business values, assuming that there were similar trends in the value of listed and unlisted enterprises.

Table 1 also shows two house price indexes, both of which show a smaller rise in the boom and a smaller decline in the bust, than we have seen for stocks. The Statistics Canada new housing price index has the obvious limitation that it is only for new houses. What we ideally would like is a quality-adjusted price index for a representative basket of existing houses. An attractive index in this context appears to be the Teranet-National Bank index, which is based on comparisons in six major cities of the prices at which the same houses sold on at least two occasions. This index of course excludes new housing, and it is this index that we use in what follows. We will also assume that other real estate had the same percentage price changes, a somewhat heroic but forgivable assumption for present purposes.

Asset Holdings in 2005

Table 2 shows the pattern of mean assets and debts within after-tax income quintiles of Canadian families in 2005.¹ The same breakdown is expressed in terms of %'s of total assets in Table 3. In viewing these tables we should keep in mind that they classify families according to current, rather than permanent or lifetime income. The lowest and highest quintiles will have disproportionate shares of those with low and high transitory income

¹ Families here are ranked simply by their total after-tax income. For a more complete analysis it would be good to also examine results when one ranks according to adult-equivalent income.

respectively. Thus the mean wealth of these groups shown here is at the bottom greater than one would expect if ranking by permanent income, and at the top less.

Table 2 shows that average family net worth in 2005 was substantial, at \$364,130, and that mean assets stood at \$421,033.² The bulk of assets, 60.6% in fact, were in non-financial form, which includes a 33.5% share for principal residences and 10.5% for business equity. Pension-type assets made up 28.6% of total assets, with about two thirds of this in the form of employer pension plans (mainly RPPs) and the remainder in RRSPs, RRIFs, and the like. Finally, directly held financial assets, including stocks and bonds, accounted for only 10.8% of the average portfolio.

As is well known there is a tendency for the kind of financial assets that are held disproportionately by the rich to be understated in household surveys. (See e.g. Davies and Shorrocks, 2000.) The value of houses, in contrast, is reported on average quite accurately. This means that the balance sheet seen in Table 2 may be somewhat short of assets like stocks and bonds, an impression that is supported by comparisons with Statistics Canada's National Balance Sheet figures, which are compiled largely from independent sources. Still, Statistics Canada has worked hard to reduce this problem, with some success. Further, the SFS has the notable advantage of including estimates of wealth held in employer pension plans, which is very important in getting a complete picture of personal wealth, and is a feature absent from the wealth surveys conducted in most other countries and prior to 1999 in Canada itself. Thus one gets a relatively complete and reasonable picture of wealth-holding from the SFS, although one should bear in mind that, like other household surveys, it is unlikely to capture the extreme upper tail of the wealth distribution very well.

Tables 2 and 3 also provide some basic information on household debts, which are fairly well captured in sample surveys. Debt is of particular interest since there has been much alarmism of late over increasing levels of household debt. We see that, at least according to

² For comparison, the National Balance Sheet estimates for persons and unincorporated businesses in the second quarter of 2005, when divided by the number of SFS families (13.1347 million) indicate figures of \$347,033 and \$418,864 for mean net worth and total assets respectively. (See earlier editions of Statistics Canada, 2009.) A difference between the SFS and the NBS is to be expected, because of differences in coverage, definitions and methods. Given these differences, the two are remarkably close on these estimates.

the SFS, household debt averaged just 13.5% of household assets in 2005, which is hardly alarming. More than half of this debt was in the form of mortgages.

Turning to the quintile breakdown, one might perhaps expect to see that lower income groups have higher debts and less in the form of financial assets than higher income groups. This expectation turns out to be false. The total debt of the bottom quintile is only 12.1 % of its assets, and both of the bottom two deciles have a larger share of their assets in financial form than the overall population. The most notable differences across the quintiles are i) the fraction of assets in pension-type form rises strongly over the first four quintiles (before declining a bit for the top quintile), and ii) the share of non-financial assets declines over the first four quintiles.

Assets and Debts in Relation to Disposable Income

While it is interesting to look at asset and debt amounts, and portfolio composition in % terms, this does not allow one to answer questions like “Do households have enough assets?” or “How long could the typical family live on its savings if it had to?” In other words, we need more information, or a different kind of information in order to appreciate the contribution of household wealth to economic security.

There are various ways of assessing the contribution of wealth to economic security. One could, for example, aggregate income and wealth by adding the annuity-equivalent value of wealth to non-investment income, in an approach pioneered by Weisbrod and Hansen (1968) and applied in Canada in a lifecycle framework by Irvine (1980). Here we try to get at the matter in a less ambitious way in Table 4, by considering the size of assets and debts in relation to disposable income.³

³ This is the same approach used by the OECD for many years in presenting its asset and debt summaries for the G7 countries. See e.g. Organization for Economic Co-operation and Development (2006), table III.1, p. 138, which reports a net wealth to disposable income ratio for Canada of 640% in 2005. Corresponding figures are given for 15 OECD countries, among which Canada ranks 8th from the top in terms of this ratio. Canadian household debts are indicated as 126% of disposable income, which is the sixth lowest debt ratio shown. The difference between these ratios and those shown here in Table 4 are due to the use of National Balance Sheet data for wealth and National Accounts data for disposable income, rather than SFS data.

Table 4 shows that the total assets and net worth of Canadian families are quite high relative to after-tax income. Overall, net worth is 742.6% of after-tax income. Absent that information, debts might seem high, at 116.1% of disposable income, but when considered in relation to the size of assets they once again do not appear too alarming. Interestingly, this favourable overall picture applies through most of the distribution. In the second quintile net worth is “only” 650.2% of income, but even that figure seems quite healthy. Looking at individual assets and asset groups we see again that pension assets mainly rise in importance with income and non-financial assets decline. The bottom quintile, on the whole, has strong holdings of financial assets, and even of deposits, which equal 95.3% of its income. While Table 4 gives us an idea of broad differences between families at different income levels, it also conceals a great deal of variation within quintiles. Part of this variation is idiosyncratic to the family unit but some is also systematically related to observable characteristics. To get some idea of the latter relationships we can examine Tables 5 and 6, which show the assets and debts of families with different characteristics. Table 5 shows amounts and Table 6 translates into %’s of after-tax income.

We find in Table 5 that unattached individuals, those whose major earner is female, and families where the major earner is less than 65 years old, all have lower wealth and assets than average. The difference is particularly large for the unattached. The same holds true for unattached individuals when we look at assets as a % of income. Overall, their net worth averages just 703.7% of disposable income, compared to 742.6% for the full sample. On the other hand, families where the major earner is female have a *higher* ratio of net worth and total assets to after-tax income than we saw for the full sample in Table 4. This may indicate justified additional caution in a group with relatively low income and greater vulnerability.

Table 6 also throws a little light on the question of whether there are particular family types that may tend to have high debt or small liquid assets, and therefore are more vulnerable to asset price or other shocks. Of the six groups identified it is the “younger” families (those below 65) who have the highest debt:income ratio (128.5%) and the lowest financial assets in relation to income. This group, for example, has bank and other deposits equal to just 22.7% of disposable income. In popular terms, they could continue their spending for less than

three months using the money they have in the bank. Of course, they also have mutual funds, stocks and other assets that could be fairly readily sold.

The over-65 major earner group as a whole appears impressively prepared for life's financial ups and downs according to these data. Even taking out their net worth in pension-type assets, which equals about five times their disposable income, they would have net worth of about ten times income. Debts for this group are on average very small. If there is cause for concern in these aggregate data it might be that employer pension plan equity equals only 341.4% of average income for the over-65 group. This reflects the fact that only a minority of workers in Canada have an employer pension plan. (In 2006, for example, only 38.1% of paid workers in Canada had an RPP. See Statistics Canada's *The Daily* for July 4, 2008.) To an extent this low incidence of pension plans is offset by the generosity of Old Age Security and the Guaranteed Income Supplement in Canada, which produce a high replacement rate of income in retirement for the bottom quintile (see LaRoche-Côté et al. 2008). However, there is a residual group of middle income families who experience a lower income replacement rate in retirement because the public programs and their private savings do not compensate them fully for their lack of an employer-based pension.

III. Asset Price Effects

Tables 7 and 8 apply the asset price changes considered above to the 2005 SFS in order to estimate the levels of assets and debts that would have been achieved at the peak of the boom, in May 2008, and in the trough of the recent bust, in February 2009. Values are given in 2005 \$'s, so that it is only changes in real asset prices that are considered here. Once again we break down families into their 2005 after-tax income quintiles.

In performing the reported calculations it is assumed that stocks, mutual funds, and business equity would all have been affected the same, and that their prices would follow the TSX. RRSPs, RRIFs, other sheltered savings, and defined contribution (DC) employer pension plans were assumed to be have 60% of their assets in stocks or mutual funds (which follows Table 7 in Statistics Canada, 2006). The remaining 40% was assumed not to be affected by

real price changes. Equity in employer pension plans was assumed to be 80% in defined benefit (DB) plans and 20% in DC or equivalent plans, following the observed division in the number of members of DB and DC plans in Canada in 2007. (Again see *The Daily*, July 4, 2008.) Prices of houses and other real estate go up at the rate shown by the Teranet-National Bank index. Remaining assets, and all debts, are assumed not to change in real value.

Table 7 shows a substantial increase in assets and net worth from the time of the 2005 SFS to the peak of the boom. Mean net worth rose to \$494,878, or by 17.5%. This is a healthy increase, especially when we consider that it is in real terms, but it is perhaps less than one might have expected in light of the much larger rise in stock prices. The explanation, of course, is that families hold a relatively small portion of their assets in stocks, directly or indirectly.

Table 8 indicates that, although the drop in asset prices after May 2008 reduced household wealth, overall what it did was to return real family wealth to the level seen in the 2005 SFS. An unpleasant surprise, of course, and more than that for those who had invested heavily in the stock market, or who had DC pension plans, but overall a kind of restoration of the status quo ante. Mean net worth in February 2009 according to these estimates would have been \$365,867 in the absence of quantity changes in asset holding (not to mention aging of the population and so on), which is as near as makes no difference to the \$364,130 found in the 2005 survey. Stocks, mutual funds, and sheltered savings plans like RRSPs would have been down significantly, yes, but non-financial assets would have risen enough to compensate - - the drop in the housing market has been much smaller than the rise from 2005 to mid 2008. And, interestingly, according to these numbers employer pension plans, overall, would have declined in value only a small amount - - by 7.1% (see Table 10). Some small redistribution from the top quintile to the rest of the population would have occurred, since the top quintile had a larger share of its assets in the stock market, directly or indirectly, but in the main the pattern of impacts would have been fairly similar across the income ranges.

It is worth commenting more on the relatively small decline of employer pension plans shown here. In the real world there is great concern about the fragility of many pension plans

at the moment. But the two things are quite consistent. The fragility of these plans is precisely due to the fact that the decline in the value of the assets held in DB plans is not passed on in formal legal terms to employees. So, the legal entitlements of the workers are not reduced - - which is what is shown in the tables here. On the other hand, a positive probability of pension plan collapse and the possibly radical reduction in benefits that would occur as a result has arisen. If one were to factor in these probabilities, then one would see a reduction in the expected value of pension rights greater than 7.1%. How large would this impact be? It is difficult to say. But suppose that 20% of the DB plans had a 50% chance of complete collapse, probably a “worst case” picture. Then this would imply a further 8% drop in the expected value of employer pension plans. Overall net worth would go down a little, but not a lot. The anxiety, insecurity and pain are highly concentrated. For those affected by the possibility of loss of pension benefits there is a huge problem. But this is not a problem that is shared by the majority of Canadians.

Finally, one can compare the simulated changes in wealth due to asset price declines found here with the changes seen in the National Balance Sheet (NBS) for persons and unincorporated businesses. The simulation here produces a 17.5% increase in net worth from June 2005 to May 2008 and a 17.5% drop thereafter to February 2009. The NBS shows a 29.0% increase in net worth from the second quarter of 2005 to the second quarter of 2008 (the data are not available monthly), and a decline of 7.3% to the end of 2008. The larger increase in NBS net worth from 2005 to the second quarter of 2008 than we simulate for the SFS could plausibly be explained by quantity increases in assets. But it is not obvious what accounts for the relatively small decrease in net worth from the second quarter of 2008 to the end of the year in the NBS.

IV. Distribution of Asset Value Declines

A shortcoming of the above analysis is that, even though we have disaggregated by quintiles, and by family types to some extent, we are still aggregating. We know that there are particular individuals and families who have been badly caught by the collapse of stock prices and by the threat of pension plan meltdowns. But they do not show up in the kind of

analysis that has been considered so far. There is a lot of room for work that would redress this balance and consider individual situations more carefully. Here we will make a small foray into this area by looking at the distribution across the SFS families of % declines in four key wealth/asset indicators that would have occurred due to asset price changes during the financial/economic crisis of 2008/09.

Table 11 shows the distribution of % asset declines from May 2008 to February 2009 that would have occurred according to the SFS data under the assumptions we have been making about asset price changes and the lack of quantity changes. The table shows that, among positive initial wealth holders, 14.5% would have seen no decline in net worth. The modal group, with 45.9% of the population, would have seen a drop of 10 to 25%. And a small group, 0.7% would have experienced a decline in net worth of more than 50%. Thus there are groups of individuals and families that have suffered very badly indeed in wealth terms from the financial/economic crisis. Their loss of economic security is not difficult to imagine.

Table 11 goes on to show the distribution of price impacts over this period for financial assets, for financial assets plus RRSPs - - “financial assets plus”, and for “financial assets plus” minus consumer and student debt. In these cases a fairly high proportion of the sample would have experienced no change, since their (mostly small) wealth is held in the form of the assets, like deposits and vehicles, that are assumed to have no real change in price. Still, 5.9% of the families would have seen a drop of 25% or more in financial assets, and 10.6% would have seen a 25% or more decline in financial assets plus RRSPs. Finally, when debts are brought in, we have a more extreme situation, with 0.5% of families seeing a 50% + decline.

That more families do not see a large decrease in financial assets is explained by the fact that participation in stocks and mutual funds is still relatively low in Canada.⁴ When it comes to financial assets, what many Canadian families have is simply deposits, Canada Savings

⁴ Statistics Canada (2006, Table 5) indicates that only 9.9% of families in the 2005 SFS held stocks directly. Mutual funds, investment funds, or income trusts were held by 14.0%.

Bonds, or GICs. These holdings were not threatened in the crisis, and the precautionary value of these assets has been well demonstrated.

V. Conclusion

What is the “bottom line” from this exercise? On the one hand, we have seen that the sharp drop in the stock market after May 2008 reduced holdings of stocks, mutual funds, and DC pension plans greatly. The value of business equity has likely also fallen by a similar percentage. Unmeasured, but nevertheless important declines in the expected value of some DB pension rights should not be discounted. And house prices have declined somewhat. It is not a good news story. But the result, in the absence of changes in asset quantities, would have been to restore mean family wealth in real terms to the level seen in the 2005 SFS. Thus, in overall terms the wealth reduction due to the crisis is a little hard to see as a great disaster.

There is pain, however, and a drop in economic security due to the effects of asset price declines. This pain is concentrated among particular groups - - for example those who invested heavily in stocks or mutual funds, defined contribution (DC) pension plan members, business owners, members of shaky defined benefit (DB) pension plans, and owners of houses and other real estate in some areas. There is much less pain among those with cautious savings/investment strategies, among members of safe DB pension plans, and others, who may form a majority of Canadian families.
